Urinary Excretion of Renal Brush-border Enzymes in Lepromatous Leprosy—a Preliminary Investigation

Majula Kohli, Chetana Vaishnavi, Uttam Chand Garg, Nirmal Kumar Ganguly, and Surrinder Kaur

Renal involvement has frequently been found to be associated with leprosy, often resulting in death (1-7). A wide variety of histopathological and immunological lesions have been reported from different geographic areas (1-8). Amyloidosis has been reported as one of the renal complications of leprosy by several workers (1, 10, 21). It is well known that secondary changes occur in the renal tubules as a result of amyloidosis. Studies conducted by Gupta, et al. (11), Grover, et al. (10), and Date, et al. (8) show 14.4%, 5.6%, and 7.5% of amyloidosis in lepromatous leprosy, respectively. Phadnis, et al. (10) observed interstitial nephritis with varying amounts of tubular degeneration in 10 out of 28 biopsies. Mittal, et al. (10) detected tubular necrosis in three cases of lepromatous leprosy, with proteinaceous casts in two of them. One report of acute tubular necrosis has also been made by one of our authors (SK) in a previous study (23). Acute tubular necrosis has recently been reported in eight cases of leprosy by Date, et al. (8). Renal biopsy is a hazardous investigation. Moreover, there is a high likelihood that the site involved may be missed altogether in a renal biopsy because of the patchy nature of the pathology.

The damaged basement membrane sheds the brush-border enzymes in diseases which involve the renal parenchyma, and these enzymes are ultimately excreted in the urine. Therefore, the presence of these enzymes in the urine may reflect the extent of renal damage. To the best of our knowledge, impairment of renal function at the enzymatic level has not been studied in leprosy patients. This report is the result of a preliminary study conducted on urine specimens obtained from lepromatous leprosy patients.

MATERIALS AND METHODS

Patients. Twenty-five patients with lepromatous leprosy (classified according to Ridley and Jopling (20)) from the leprosy clinic of the Nehru Hospital attached to the Postgraduate Institute of Medical Education and Research, Chandigarh, India, were studied. All patients were freshly diagnosed, untreated for leprosy, had not taken any other drugs during the past 6 months, and none had any other disease which could affect the kidneys. A 24-hr urine sample was collected in a sterilized container with sodium azide (1 g/l) to prevent contamination. The collections were done after hospitalization of the patients, and the samples were kept refrigerated (4°C) and assayed in an air-conditioned room (cold room). The samples were assayed within 3 months of collection. The samples were centrifuged at 15,000 rpm and dialyzed against distilled water for 2 hr before the estimations of the enzymes were undertaken.

Controls. Twenty-five age-, sex-, and socioeconomic status-matched healthy individuals served as controls.

**Estimation of brush-border enzymes.** The enzymes studied were: a) alkaline phosphatase (Alph) (2); b) gamma-glutamyl transpeptidase (GGT) (18); c) leucine aminopeptidase (LAP) (9); and d) maltase (M) (4). Each enzyme was assayed in triplicate. The substrates used (Boehringer, Mannheim, West Germany) were: a) p-nitrophenyl phosphate in 0.5 M glycine buffer for Alph; b) gamma-glutamyl p-nitroaniline in Tris-HCl buffer,
Kohli, et al.: Renal Brush-border Enzymes in Urine

pH 7.0, for GGT; c) L-leucine-p-nitroanilide for LAP; and d) maltose for M. The enzymatic activities were estimated spectrophotometrically (LKB-Biochrom Ultraspec 4050) as determined by the colored products formed. The 24-hr urinary protein was also estimated by the method of Lowry, et al. (15).

RESULTS

The activities of the different renal brush-border enzymes estimated are shown as µmol/min/mg protein in the Figure. The highest value obtained for the control subjects in every estimation has been taken as the cut-off point for better comparison, and values beyond this were taken as positive. A significant increase (p < 0.01) was seen in the activities of alkaline phosphatase, leucine aminopeptidase, and gamma-glutamyl transpeptidase in the leprosy group compared to controls. The increase in excretion of maltase was statistically even more pronounced (p < 0.001) in the leprosy group compared to controls. The mean values of the 24-hr urinary protein estimated (0.26 ± 0.11 mg/ml with a range of 0.11-0.56 mg/ml) in leprosy patients were increased (p < 0.001) when compared to those of the control samples (0.11 ± 0.03 mg/ml with a range of 0.05-0.2 mg/ml).

DISCUSSION

A high incidence of renal abnormalities is reported to occur in lepromatous leprosy (7, 12), indicating that the kidney is one of the target organs involved and that it is rendered more susceptible to systemic infections during the course of the disease. The histopathological aspects of renal involvement in leprosy do not, by themselves, explain the complete renal pathogenesis.

In the present investigation, 11–15 out of 25 lepromatous leprosy patients studied showed increased quantities of kidney-associated enzymes in their urine. No other evidence of renal disease was seen. Hence, it may be presumed that the patients in whom high levels of urinary enzymes were detected are in the preclinical stage of tubular damage probably related to their lepromatous leprosy. Gamma-glutamyl transpeptidase, one of the most important renal brush-border enzymes, was excreted in almost every patient. The effect of treatment on the rate of excretion of these enzymes might be useful in a follow-up study.

Studies of the urinary excretion of brush-border membrane enzymes has been carried out both in animals and in man (17, 24). Studies in lithium-administered rats have indicated that the urine enzyme assay is a valuable tool for detecting renal damage (8). Jung, et al. (13) have studied the enzymatic activities in patients with chronic glomerulonephritis and chronic pyelonephritis and found that the diagnostic importance obtained from an estimation of total activity can be further improved by separating the enzymes into soluble and particulate forms.

Systemic infections such as leprosy can cause necrosis of the proximal tubules, resulting in shedding of the enzymes into the urine. The detection of enzymuria may have many implications. It might be helpful in follow-up studies of patients under treatment or, alternatively, to check for relapses because the release of kidney-associated enzymes can well be a marker of ongoing active damage. It is possible that the tubular damage picked up from the shedding of the epithelial membrane (and consequently the enzymes) might be occurring prior to the histopathological damage, and thus enzym-
uria might be useful as an early marker of renal damage.

**SUMMARY**

Activities of the brush-border enzymes, alkaline phosphatase, maltase, leucine aminopeptidase, and gamma-glutamyl transpeptidase, were measured in urine samples of 25 lepromatous leprosy patients and an equal number of age-matched healthy controls. None of the patients were shown to be suffering from any other systematic disease. The enzymatic activities were shown to be significantly elevated in leprosy patients when compared to controls.

**RESUMEN**

Se midieron las actividades de las enzimas fosfatasa alcalina, maltasa, leucin aminopeptidasa y gamma-glutamínil transpeptidasa, en la orina de 25 pacientes con lepra lepromatosa y en 25 controles sanos apareados por edad. Ninguno de los pacientes presentaba ninguna otra enfermedad sistémica al tiempo del estudio. Se encontró que las actividades enzimáticas estuvieron significativamente incrementadas en el grupo de pacientes con lepra.

**RÉSUMÉ**

Dans des échantillons d’urine provenant de 25 maladies atteints de lèpre lepromateuse et d’un nombre égal de témoins en bonne santé assortis pour l’âge, on a mesuré l’activité d’une série d’enzymes de la bordure en brosse, la phosphatase alcaline, la maltase, la leucine aminopeptidase, et la gamma-glutamyl transpeptidase. On n’a mis en évidence aucune autre maladie systémique chez ces malades. Les activités enzymatiques étaient significativement augmentées chez les malades de la lèpre, par comparaison avec les témoins.
